Ab initio investigation of the exchange interactions in Bi$_2$Fe$_4$O$_9$:

The Cairo pentagonal lattice compound

We present the ab initio calculation of the electronic structure and magnetic properties of Bi$_2$Fe$_4$O$_9$. This compound crystallizes in the orthorhombic crystal structure with the Fe$^{3+}$ ions forming the Cairo pentagonal lattice implying strong geometric frustration. The neutron diffraction measurements reveal nearly orthogonal magnetic configuration, which at first sight is rather unexpected since it does not minimize the total energy of the pair of magnetic ions coupled by the Heisenberg exchange interaction. Here, we calculate the electronic structure and exchange integrals of Bi$_2$Fe$_4$O$_9$ within the LSDA + U method. We obtain three different in-plane ($J_1 = 36$ K, $J_4 = 73$ K, $J_5 = 23$ K) and two interplane ($J_1 = 10$ K, $J_2 = 12$ K) exchange parameters. The derived set of exchange integrals shows that the realistic description of Bi$_2$Fe$_4$O$_9$ needs a more complicated model than the ideal Cairo pentagonal lattice with only two exchange parameters in the plane. However, if one takes into account only the two largest exchange integrals, then according to the ratio $x \equiv J_1/J_4 = 0.49 < \sqrt{2}$ (a critical parameter for the ideal Cairo pentagonal lattice, see Rousouchatzakis, Läuchli, and Moessner, Phys. Rev. B 85, 104415 (2012)) the ground state should be the orthogonal magnetic configuration in agreement with experiment. The microscopic origin of different exchange interactions is also discussed.

I. INTRODUCTION

Until D. Shechtman discovered quasicrystals (the Nobel Prize in Chemistry in 2011), it was thought that it is impossible to pack atoms into a regular lattice and obey pentagonal symmetry. This type of symmetry is not rare in the nature. It can be found in wild flowers and many sea dwellers as well as in a scale of a fir cone and a pineapple. The only known naturally occurring quasicrystal phase is the icosahedrite (Al$_{63}$Cu$_{24}$Fe$_{13}$) (Petrussov, W. Furtak, and D. Shechtman, J. Solid State Chem. 27, 35 (1978); Shechtman et al., Phys. Rev. Lett. 53, 1951 (1984)).

We present the ab initio calculation of the electronic structure and magnetic properties of Bi$_2$Fe$_4$O$_9$. This compound crystallizes in the orthorhombic crystal structure with the Fe$^{3+}$ ions forming the Cairo pentagonal lattice implying strong geometric frustration. The neutron diffraction measurements reveal nearly orthogonal magnetic configuration, which at first sight is rather unexpected since it does not minimize the total energy of the pair of magnetic ions coupled by the Heisenberg exchange interaction. Here, we calculate the electronic structure and exchange integrals of Bi$_2$Fe$_4$O$_9$ within the LSDA + U method. We obtain three different in-plane ($J_1 = 36$ K, $J_4 = 73$ K, $J_5 = 23$ K) and two interplane ($J_1 = 10$ K, $J_2 = 12$ K) exchange parameters. The derived set of exchange integrals shows that the realistic description of Bi$_2$Fe$_4$O$_9$ needs a more complicated model than the ideal Cairo pentagonal lattice with only two exchange parameters in the plane. However, if one takes into account only the two largest exchange integrals, then according to the ratio $x \equiv J_1/J_4 = 0.49 < \sqrt{2}$ (a critical parameter for the ideal Cairo pentagonal lattice, see Rousouchatzakis, Läuchli, and Moessner, Phys. Rev. B 85, 104415 (2012)) the ground state should be the orthogonal magnetic configuration in agreement with experiment. The microscopic origin of different exchange interactions is also discussed.

with the fourfold ones ($J_{13}$ exchange path). Such a Cairo pentagonal lattice has the square Bravais lattice and the unit cell containing four fourfold- and two threefold-coordinated sites. The phase diagram of the AFM Heisenberg model was obtained as a function of the ratio $x \equiv J_{13}/J_{33}$ and spin $S$. In the classical limit (large $S$), three magnetic phases have been found: (1) a phase, where the spins on the neighboring sites are orthogonal to each other ($x < \sqrt{2}$), (2) the collinear 1/3-ferrimagnetic phase ($x > 2$), and (3) an intermediate mixed phase ($\sqrt{2} < x < 2$), which is a combination of (1) and (2).

At present, there are known only two complex iron oxides that represent the physical realization of the magnetic Cairo pentagonal lattice, namely Bi$_2$Fe$_2$O$_5$ and Bi$_4$Fe$_3$O$_{13}$. Bi$_2$Fe$_2$O$_5$ can be obtained as a byproduct in the synthesis of the multiferroic BiFeO$_3$ and seems to reveal multiferroic properties by itself. It is also regarded as a perspective material for the semiconductor gas sensors.

Bi$_2$Fe$_2$O$_5$ crystallizes in the complex orthorhombic structure with the space group $Pbam$ (No. 55). It has two formula units in the unit cell and two nonequivalent iron atoms Fe$_t$ and Fe$_o$ occupying the tetrahedral and octahedral positions, correspondingly (see Fig. 1). The edge-sharing Fe$_o$O$_6$ octahedra form the chains along the $c$ direction and these chains are bound by the corner-sharing Fe$_t$O$_5$ tetrahedra and Bi atoms. Fe$_o$ occupies aforementioned threefold-coordinated sites, while Fe$_t$ fourfold.

The magnetic measurements on a single crystal were performed in Ref. 7. At high temperature, a Curie-Weiss fitting of the magnetic susceptibility gives the paramagnetic temperature $\theta_p \approx -1670$ K and the effective magnetic moment $\mu_{eff} = 6.3(3)\mu_B$ per iron atom in agreement with value $5.9\mu_B$ corresponding to $S = 5/2$ of the Fe$^{3+}$ ions. The long range magnetic order with $T_N = 238$ K sets in at much lower temperature indicating the presence of magnetic...
FIG. 1. (Color online) The crystal structure of Bi$_2$Fe$_4$O$_9$ along the $c$ axis (upper panel) and in the $ab$ plane (lower panel). There are two types of the Fe ions: Fe$_o$ is placed in the oxygen octahedra (blue), while Fe$_t$ is in the ligand tetrahedra (green). O and Bi are shown as red and yellow balls, respectively. $J_1$ and $J_2$ are the interplane exchange interactions. We use VESTA software$^8$ for visualization.

frustrations in the system. In the unusual nearly orthogonal magnetic structure at low temperatures, the moments on all the iron atoms lying in the $(a,b)$ plane. The Fe$_o$ spins form four orthogonal sublattices while the Fe$_t$ spins align antiferromagnetically with each other (see Fig. 2).

In contrast to the perfect Cairo lattice model studied in Ref. 2, the real orthorhombic crystal structure of Bi$_2$Fe$_4$O$_9$ has few distinct features. Namely, each pentagonal unit cell contains seven sites because there are two Fe$_o$ ions in the center of the unit cell (see Fig. 1) with different coordinates along the $c$ axis, while the ideal structure has only one. Hence, for the realistic treatment of the magnetic interactions, one needs to calculate at least five different exchange constants, which can hardly be done reliably by fitting the model solutions of the Heisenberg Hamiltonian to the magnetic susceptibility or other experimental observables. Such a fitting allows however to estimate the ratio between some of the exchange integrals.$^7$

In this paper, we present an ab initio calculation of the exchange constants in Bi$_2$Fe$_4$O$_9$, compare the result obtained with available theoretical and experimental data, show that this system cannot be considered as a realization of the perfect Cairo pentagonal lattice, and discuss the microscopic mechanisms that define the strength of different magnetic interactions.

II. CALCULATION DETAILS

We used the linearized muffin-tin orbitals method (LMTO)$^9$ with the von Barth-Hedin version of the exchange correlation potential$^{10}$ to calculate the electronic and magnetic properties of Bi$_2$Fe$_4$O$_9$. In order to take into account strong electronic correlations on the Fe sites, the LSDA + $U$ approximation was applied$^{11}$ with the on-site Coulomb repulsion parameter $U = 4.5$ eV and the intra-atomic Hund’s rule exchange $J_H = 1$ eV.$^{12-14}$ We also checked how stable is the result with respect to the small variations of the $U$ and $J_H$ parameters, since the value of $U$ may be different in different systems.$^{15}$ The double counting term corresponding to the fully localized limit was used according to Ref. 11.

The Liechtenstein’s exchange interaction parameter (LEIP) calculation procedure$^{16}$ was used to find the intrasite exchange constants for the classical Heisenberg model written as

$$H = \sum_{ij} J_{ij} \vec{S}_i \cdot \vec{S}_j,$$  

(1)

where each site in the summation is counted twice. According to this method, exchange constants $J$ can be calculated as the second derivative of the total energy variation at small spin
rotation. This allows to (1) calculate all $J$ in one magnetic configuration and (2) check whether a given spin structure corresponds to the ground state or spins on some of the sites must be reversed. The later is seen from the sign of the exchange constant: where all pairs of Fe$^3_-$-Fe$^3_+$ are antiferromagnetically ordered, the exchange constant for a given bond in another spin structure, since the curvature of the total energy surface and hence the value of $J$, in general, can be different for minima and maxima.

For the calculation of the exchange constants between the tetrahedral and octahedral Fe ($J_3$ and $J_2$ in Fig. 2), we used the magnetic configuration, where the spins on these bonds are antiferromagnetically coupled, but then the pairs of two tetrahedral Fe's ($J_2$) turn out to be ferromagnetically ordered. The calculation using the LEIP method shows that the signs for $J_2$ and $J_3$ are correct (positive) for this order, but the direction of one of the spins forming $J_2$ path must be reversed. By checking few other magnetic configurations where spins on the Fe$^3_-$-Fe$^3_+$ bond were antiferromagnetically ordered, we found that in this case, the LEIP method gives positive $J_4$, and its value is the same in these calculations. The same procedure was repeated for the interplane exchange coupling $J_1$ and $J_5$. Since the signs provided by the LEIP procedure do not correspond to the usual conventions, in the following the positive (negative) exchange constants will mean antiferromagnetic (ferromagnetic) $J$ according to the Heisenberg model presented in Eq. (1).

The crystal structure was taken from Ref. 6 and is shown in Fig. 1. The mesh of 144 $k$ points in the Brillouin zone was used in the course of the self-consistency.

### III. RESULTS

The total and partial densities of states (DOS) obtained in the LSDA $+ U$ calculation for the magnetic configuration, where all pairs of Fe$^3_-$-Fe$^3_+$, are antiferromagnetically ordered are presented in Fig. 3. The DOS obtained for other magnetic structures are quite similar. The top of the valence band is mostly defined by the O $2p$ states, while the bottom of the conduction band is formed by the Fe $3d$ (spin minority) states. So that Bi$_2$Fe$_4$O$_9$ must be classified as a charge transfer insulator. The band gap varies from 0.97 to 1.28 eV depending on the magnetic configuration under consideration. The values of the spin moments are slightly reduced from 5 $\mu_B$ expected for the Fe$^{3+}$ ions with $S = 5/2$ due to the hybridization effects and equal 3.9–4.0 $\mu_B$.

There are three different types of the exchange coupling in the $ab$ plane according to our calculations [see Table I (first string) and Fig. 2]. The largest is $J_1 = 73$ K for the pair of the tetrahedral Fe$_t$. There are also two $J_2 = 23$ K and two $J_3 = 36$ K both between the octahedral and tetrahedral Fe ions. The main mechanism for all of them is the superexchange via oxygen ion shared by two FeO$_6$(4) polyhedra. The values of these three exchange constants are different because of the quite different geometry of the Fe-O-Fe bonds and the ligand polyhedra surrounding each Fe ion.

The exchange constant between two tetrahedral Fe$_t$ ions is the largest, because of the strong $t_{2g}/t_{2g}$ exchange coupling. The $t_{2g}$ orbitals are directed as much as possible to the oxygens in the tetrahedral case and three $t_{2g}$ orbitals on each Fe$_t$ site take part in a strong superexchange with the $2p$ orbitals of a common O, via the 180° Fe-O-Fe bond. The direct calculation using LEIP procedure shows that $J_{t_{2g}/t_{2g}} = 50$ K, whereas $J_{t_{2g}/t_{2g}} = 16$ K and $J_{t_{2g}/t_{2g}} = 7$ K (see Table III).

If the coordinate system is chosen in a way shown in Fig. 4, it is convenient to work not with the conventional $p_x$, $p_y$, and $p_z$ orbitals, but with $p_x = (p_x + p_y + p_z)/\sqrt{3}$, $p_1 = (p_x - p_y)/\sqrt{2}$, and $p_2 = (p_x + p_y - 2p_z)/\sqrt{6}$. Then the largest $p$-$d$ hopping in the tetrahedra will be between $p_1$ and any of the $t_{2g}$

![FIG. 3. (Color online) The total and partial density of states plot obtained in the LSDA $+ U$ calculation for the magnetic configuration, where all Fe$_t$ and Fe$_o$ are antiferromagnetically ordered. The positive (negative) values correspond to the spin up (down). The Fermi energy is in zero.](attachment:image.png)
orbs (different $p$-$t_{2g}$ hopping matrix elements in the case of a regular tetrahedron are calculated in Table II with the use of the Slater-Koster parametrization\(^\text{18}\)). Hence the Largest contribution to the total exchange interaction between two tetrahedral Fe\(_o\) will be the superexchange via the $p_\sigma$ orbital:

$$J^{t_{2g}/p_\sigma}_{t_{2g}/t_{2g}} \sim \frac{g(t_{pd\sigma})^2 (t_{pd\pi})^2}{U \Delta_{CT}^2},$$

(2)

where $\Delta_{CT}$ is the charge transfer energy (energy of the excitation from the O $2p$ orbitals to the 3d shell of a transition metal ion, in our case, Fe\(^{3+}(d^6)\)O\(^2-\)($2p^6$) → Fe\(^{2+}(d^6)\)O\(^-$($2p^5$)\)).

It is interesting that Eq. (2) can be rewritten in a more useful form if one will use a basis of the trigonal-like\(^\text{20}\) orbitals also for the 3d states, i.e., $a_{1g} = (d_{x^2} + d_{y^2} + d_{z^2})/\sqrt{3}$, $t_1 = (d_{x^2} - d_{y^2})/\sqrt{2}$, and $t_2 = (d_{x^2} + d_{y^2} - 2d_{z^2})/\sqrt{6}$. Then, all $t_{pd}$ hopping parameters will be zero except $t_{p_{\sigma}a_{1g}} = t_{pd\sigma}$, $t_{p_{\delta}t_1} = t_{pd\delta}/\sqrt{3}$ and there will be only two contributions to the exchange between the $t_{2g}$ orbitals coming from the $a_{1g}$ orbitals:

$$J_{t_{2g}/a_{1g}} \sim \frac{(t_{pd\sigma})^2}{U \Delta_{CT}^2},$$

(3)

### Table II. The values of the $p$-$d$ hopping matrix elements ($t_{pd}$) between the $d$ and $p$ orbitals ($p_\sigma = (p_x + p_y + p_z)/\sqrt{3}$, $p_1 = (p_x - p_y)/\sqrt{2}$, and $p_2 = (p_x + p_y - 2p_z)/\sqrt{6}$) in the case of the regular M\(_{O_4}\) tetrahedron using the Slater-Koster parametrization,\(^\text{18}\) if the coordinate system is chosen as shown in Fig. 4.

and from the $t_1$ and $t_2$ orbitals,

$$J_{t_{2g}/a_{1g}} \sim \frac{2(t_{pd\sigma})^4}{9U \Delta_{CT}^2},$$

(4)

Using the estimation of the interatomic matrix elements,\(^\text{19}\) it is easy to find that the ratio

$$\frac{J_{t_{2g}/a_{1g}}}{J_{t_{2g}/p_\sigma}} \sim 100,$$

(5)

so that one may think that in the case of the regular tetrahedra the $t_{2g}/t_{2g}$ exchange with a good precision can be described solely by the superexchange between the $a_{1g}$ orbitals via the $p_\sigma$ orbital.

Since $J_4$ is considerably larger than other in-plane exchange couplings, it fixes the directions of the spin moments on two out of three tetrahedral Fe sites, i.e., makes spins of these Fe ions antiparallel. The exchange constants $J_4$ and $J_5$ describing coupling between the octahedral Fe\(_o\) and tetrahedral Fe\(_t\) ions are noticeably smaller than $J_4$ for the pair of the tetrahedral Fe\(_t\). There are two reasons for that.

First of all, the angle of the Fe\(_t\)-O-Fe\(_o\) bond is far from 180° (the Fe\(_t\)-O-Fe\(_o\) bond angle is exactly 180°). If it was ~180° then the superexchange between the Fe\(_o\) $t_{2g}$ and Fe\(_t\) $e_\pi$ states via the O $p_\sigma$ orbital would be of the order of the $t_{2g}/t_{2g}$ superexchange in the pair of the tetrahedral Fe\(_o\), [the number of active orbitals (two $e_\pi$ orbitals) of the octahedral Fe\(_o\) will be smaller than in the tetrahedral case (three $t_{2g}$ orbitals), but they will be directed exactly to the oxygens]. However, this is not the case. There are two types of the tetrahedron-octahedron bonds in Bi\(_2\)Fe\(_4\)O\(_9\) structure: one with the Fe\(_o\)-Fe\(_o\) angle $\alpha_1 \sim 120^\circ$ and another with $\alpha_2 \sim 130^\circ$ (see Fig. 1). The first one provides exchange coupling $J_5$, while the second $J_3$. Since $\alpha_1,2$ are far from both 180° and 90°, the $t_{2g}/t_{2g}$ and $t_{2g}/e_\pi$ superexchanges should be comparable. The direct calculation using LEIP formalism (see Table III) shows that for the 120° bond: $J_5^{t_{2g}/t_{2g}} = 8$ K and $J_5^{t_{2g}/e_\pi} = 8$ K, while for the 130° bond $J_5^{t_{2g}/t_{2g}} = 13$ K and $J_5^{t_{2g}/e_\pi} = 15$ K. Note, that the contribution coming from the $e_\pi$ orbitals is surprisingly almost the same for these two exchange pairs: $J_5^{t_{2g}/e_\pi} = 7$ K and $J_5^{t_{2g}/e_\pi} = 8$ K.

The second important difference between exchanges in the Fe\(_o\)-Fe\(_o\), Fe\(_o\)-Fe\(_t\), and Fe\(_o\)-Fe\(_o\) pairs is in the Fe-O bond distance. In the case of two tetrahedral Fe\(_o\) ions both Fe\(_o\)-O bond distances are $d(\text{Fe}_o\text{-O}) = 1.81$ Å. While for the Fe\(_o\)-Fe\(_t\) pair in the case of the bond angle $\alpha_1 = 120^\circ$ ($J_5$): $d(\text{Fe}_o\text{-O}) = 1.91$ Å and $d(\text{Fe}_o\text{-O}) = 2.03$ Å, while for $\alpha_2 = 130^\circ$ ($J_3$): $d(\text{Fe}_o\text{-O}) = 1.85$ Å and $d(\text{Fe}_o\text{-O}) = 1.97$ Å. The Fe\(_o\)-O bond distances are larger than Fe\(_t\)-O since the ionic radius of the Fe\(_{3+}\) is larger in.
the octahedral coordination than in tetrahedral \[ R_{\text{HS}(\text{Fe}^{3+})}^{\text{IV}} = 0.49 \text{ Å}, \text{ while } R_{\text{HS}(\text{Fe}^{3+})}^{\text{VI}} = 0.645 \text{ Å}. \]

It is rather complicated to find analytically the bond and angle dependencies of all exchange constants due to the strongly distorted crystal structure and many active (magnetically) orbitals in Bi$_2$Fe$_4$O$_9$. We performed such calculations for the $t_{2g}/e_g$ contribution to the exchange coupling between the octahedral and tetrahedral Fe ions with the 130° and 120° Fe-O-Fe bonds angles. Within the fourth order of the perturbation theory and using the approximations that, as it was shown above, the Fe-O hoppings occur only via the $p_a$ orbital and that depend only on the Fe-O bond distance, one may find that

\[ J_{10}^{t_{2g}/e_g} \sim \sum_i \left( \frac{\text{Int}(p_{a_{i,t_{2g}}})}{U \Delta_{\text{CT}}} \right)^2 \sum_i C \left( \frac{\text{Int}(p_{a_{i,e_g}})}{U \Delta_{\text{CT}}} \right)^2, \tag{6} \]

where $i$ numerates the $e_g$ orbitals of the octahedral Fe$_{\text{o}}$. The $t_{2g}/e_g$ can be estimated using the Slater-Koster coefficients and atomic positions of the Fe and O ions. Then, if one takes into account only the angle dependence of the hopping matrix elements, \[ J_{10}^{t_{2g}/e_g}(130°)/J_{10}^{t_{2g}/e_g}(120°) = 1.45. \]

The bond length dependence can be found using the Harrison parametrization of the $pd$ hopping integrals ($t_{pd} \sim \frac{1}{\Delta}$), which gives

\[ J_{10}^{t_{2g}/e_g}(130°)/J_{10}^{t_{2g}/e_g}(120°) = 1.22. \]

Taking into account both mechanisms (the angle and bond length dependence) one finds that this ratio is $\sim 1.8$, which agrees reasonably with the same ratio, obtained in the LSDA + $U$ calculation, which equals 1.9.

Calculated exchange constants are in qualitative agreement with the estimations made in Ref. 7. All exchange constants in the $ab$ plane are antiferromagnetic and the ratio of two tetrahedral-octahedral exchange constants $J_3/J_5 \approx 1.6$ (2.15 in Ref. 7). Because of the difference between $J_1$ and $J_5$ Bi$_2$Fe$_4$O$_9$ cannot be considered as a perfect realization of the Cairo pentagonal lattice, but still the deviations are not so strong, and it makes sense to compare our situation with that of the ideal lattice. There are only two exchange constants in the perfect version of this lattice $J_1$ and $J_5 = J_3$. The model study of the magnetic properties of the ideal Cairo pentagonal lattice shows that its ground state corresponds to the orthogonal spin order, if $J_3/J_1 < \sqrt{2}$. According to our calculations both $J_5/J_3 \approx 0.32$ and $J_5/J_4 \approx 0.49$ are less than $\sqrt{2}$, and hence the ground state is also expected to be described by the orthogonal spin order, exactly as it was observed experimentally.

There are two types of the exchange constants that couple the octahedral Fe$_{\text{o}}$ ions along the $c$ axis. The first one, $J_1$ (Fe$_{\text{o}}$-Fe$_{\text{o}}$ bond distance 2.90 Å), actually has to be considered as a part of the pentagonal lattice (see Fig. 2). This constant is antiferromagnetic and equals $J_1 = 10$ K, almost a half of one of the in-plane exchanges ($J_5$). It brings additional (to pentagonal) frustration in the spin system, since there are four antiferromagnetic triangles linked with each pentagon, see Fig. 2. The second interplane exchange, $J_2 = 12$ K (Fe$_{\text{o}}$-Fe$_{\text{o}}$ bond distance 3.10 Å), is antiferromagnetic as well and couples different pentagonal planes with each other.

Finally, in order to show the dependence of the exchange constants on the $U$ and $J_H$ parameters, we performed the calculations with $U = 5.5$ eV instead of 4.5 eV (with $J_H = 1$ eV) and with $J_H = 0.9$ eV instead of 1 eV (with $U = 4.5$ eV). In the first case, $J_1 = 9$ K, $J_2 = 9$ K, $J_3 = 31$ K, $J_4 = 64$ K, and $J_5 = 19$ K, while in the second case, $J_1 = 10$ K, $J_2 = 12$ K, $J_3 = 36$ K, $J_4 = 72$ K, and $J_5 = 22$ K (see Table I). So that one may see that a small modification of $J_H$ does not change the value of exchange constants, while they are decreased as $U$ increases, since all of the $J$s are inversely proportional to $U$.

**IV. CONCLUSIONS**

In the present paper, we carried out the band structure calculations of Bi$_2$Fe$_4$O$_9$ and found that it must be classified as a charge transfer insulator. The investigation of the exchange constants shows that this compound cannot be considered as a perfect realization of the Cairo pentagonal lattice. First of all, there are two different exchange parameters between the tetrahedral and octahedral Fe ions. Second, the interplanar exchange coupling additionally frustrates the system. The exchange constants along the $c$ axis are not negligibly small and exceed 50% of one of the intraplanar exchange ($J_3$). However, in spite of these findings, Bi$_2$Fe$_4$O$_9$ still demonstrates nearly orthogonal spin order below $T_N = 7$ K in accordance with the results obtained in Ref. 2, where the study of the perfect Cairo pentagonal model was performed. This is due to the fact that both exchange parameters between the tetrahedral and octahedral Fe ions ($J_3$ and $J_5$) are much smaller than the magnetic coupling between the tetrahedral Fe sites ($J_4$). Strong $J_4$ makes the spins on two out of three tetrahedral sites antiparallel, while the ratio between $J_3$ and $J_5$ defines the angles between spin moments on the rest, one tetrahedral and two octahedral Fe sites. The microscopic analysis shows that the largest contribution, $\sim 70\%$, to $J_4$ comes from the coupling between the $t_{2g}$ orbitals on different sites. The deviations from the perfect Cairo pentagonal model are expected for more subtle characteristics such as, e.g., low-energy excitation spectra. However, for the full description of the magnetic properties of Bi$_2$Fe$_4$O$_9$, the calculation of the single-ion anisotropy and anisotropic exchange constants can be required.
