(Rceived 28 June 2012; revised manuscript received 6 August 2012; published 21 August 2012)

The magnetic and electronic properties of Ba$_4$Ru$_3$O$_{10}$ were investigated by the ab initio and model calculations. It is shown that nonmagnetic ground state of the one-third Ru$^{4+}$ ions is not due to the correlation effects. It is rather caused by the charge disproportionation between crystallographically different Ru and the molecular orbital formation in the Ru’s trimer.

I. INTRODUCTION

The complex Ru oxides are widely investigated in the past decades because of their unusual electronic and magnetic properties. The odd-parity pairing was found in the superconductor Sr$_2$RuO$_4$, while Ca$_2$RuO$_4$ became one of the model systems for study of the orbital-selective Mott transition. The integer spins on the Ru$^{4+}$ ions likely form the Haldane chains in Tl$_2$Ru$_2$O$_7$, which leads to a drastic decrease of the magnetic susceptibility at low temperatures. Similar behavior of susceptibility was recently observed in another Ru oxide—Ba$_4$Ru$_3$O$_{10}$. This drastic decrease was initially attributed to the formation of the unconventional antiferromagnetic (AFM) state, but the mechanism of its stabilization is still unknown.

Structurally Ba$_4$Ru$_3$O$_{10}$ is made of the Ru trimers. These trimers are formed by three RuO$_6$ octahedra sharing their faces. Each trimer is connected with four neighboring trimers (see Fig. 1) via corners of the outer RuO$_6$ octahedra to build corrugated layers. We denote the middle Ru ion in the trimer Ru$_m$, while two outer Ru$_o$.

In Ba$_4$Ru$_3$O$_{10}$ the Ru ions must have 4+ oxidation state with four electrons in the 4$d$ shell, since Ba is 2+ and O is 2−. Due to a large $t_{2g}$-$e_g$ crystal-field splitting (see Sec. III for details) these four 4$d$ electrons should be stabilized in the $t_{2g}$ subshell resulting in the state with $S = 1$. Indeed, at room temperature Ba$_4$Ru$_3$O$_{10}$ was found to be paramagnetic with the effective moment $\mu_{eff} = 2.83 \mu_B$ typical for the $S = 1$ ions, while the decrease of the temperature below $T_K = 105$ K leads to the formation of the unconventional AFM state, where one-third of the Ru$^{4+}$ ions are not ordered (tentatively these are Ru$_m$).

Several models were proposed in Ref. 4 to explain this physical phenomenon. One may think that (1) due to some reason a part of the Ru ions stays paramagnetic down to a very low temperature; (2) they are randomly frozen; or (3) because of a strong spin-orbit coupling a nonmagnetic state of the Ru ion with $J = 0$ is stabilized.

In order to check all these possibilities, the ab initio band-structure calculations were performed for this compound. We found that the true reason for the absence of the magnetic moments on one-third of the Ru ions is the charge disproportionation between two crystallographically nonequivalent Ru (Ru$_m$ and Ru$_o$) and formation of the molecular orbital in the trimers. In the band-structure picture it is manifested in the suppression of the nonmagnetic 4$d$ density of states (DOS) of the middle Ru$_m$ in the vicinity of the Fermi level.

II. CALCULATION DETAILS

For the band-structure calculations we primarily used the pseudopotential PWscf code. We utilized the generalized gradient approximation (GGA) with Perdew-Burke-Ernzerhof version of the exchange-correlation potential and ultrasoft scalar-relativistic pseudopotentials with nonlinear core correction (for better description of the magnetic interactions). The charge density and kinetic energy cutoffs were taken as 40 Ry and 200 Ry, respectively. The mesh of $6 \times 6 \times 4$ $k$-points in a full Brillouin zone was used in the calculation.

The generalized gradient approximation with the account of the on-site Coulomb repulsion (GGA+$U$ method) was used to test an importance of the electronic correlations. The Hubbard’s on-site repulsion parameter $U$ and Hund’s rule intra-atomic exchange $J_H$ for Ru were calculated in Ref. 3 to be 3.0 eV and 0.7 eV.

The Wannier function projection was performed within the linearized muffin-tin orbitals (LMTO) method as described in Ref. 10.

All the calculations were performed for the crystal structure corresponding to $T = 10$ K.

III. NONMAGNETIC GGA CALCULATIONS

We start with the analysis of the results obtained in the nonmagnetic generalized gradient approximation (GGA), presented in Fig. 2. One may see that the oxygen 2$p$ states are placed primarily from −7 to approximately −1 eV. The top of the valence band is formed by Ru-4$d$ ($t_{2g}$) states. The Ru-$e_g$ orbitals are above 1.5 eV. The $t_{2g}$-$e_g$ crystal field splitting estimated by the center of gravity calculation is 3.38 and 3.20 eV for Ru$_m$ and Ru$_o$, respectively. Thus one would indeed expect that such a strong crystal field splitting would prevent occupation of the $e_g$ orbitals and $d^0$ configuration of Ru$^{4+}$ would result in the $S = 1$ ground state of each Ru ion.

However, there is another quite important feature of the nonmagnetic DOS related to the splitting between the Ru$_m$ and Ru$_o$ 4$d$ states, which is clearly seen from Fig. 2. The same center of gravity calculation shows that this splitting exceeds...
FIG. 1. (Color online) Crystal structure of Ba₄Ru₃O₁₀. Projection on the bc plane. Oxygen ions are in blue, ruthenium in red, and Ba not shown for the simplicity. Ruₘ are in the middle of the trimers; Ruₒ are on the corners.

0.13 eV. The Ruₘ-4d states integrally turn out to be lower than Ruₒ-4d due to a larger mean Ru-O distance. According to Ref. 4, the difference in the mean Ru-O distances for these two Ru exceeds 0.035 Å. This is not a small number, since the difference in ionic radii between Ru⁴⁺ and Ru³⁺ is 0.06 Å.¹¹ As a result one could expect that there would be more d electrons on the middle Ru, i.e., it would have on the average a smaller valence. And, indeed, according to our nonmagnetic GGA calculations the difference in charge between Ruₘ and Ruₒ is 0.52 electron per atom, which is even larger than the charge disproportionation on the Fe sites in the charge ordered phase of Fe₃O₄.¹²

Thus Ruₘ-t₂g partial DOS states turn out to be almost completely below the Fermi level, except for a small shoulder and a narrow peak at ~0.9 eV. The detailed analysis of the band structure, presented in Fig. 3, confirms that the band corresponding to this peak in DOS at 0.9 eV is dispersionless. One may also see that each band in the ZT direction is two times degenerate, since there are two formula units (f.u.) in the unit cell. In effect each trimer provides one dispersionless band at ~0.9 eV.

In order to analyze the formation of this band we carried out the calculation within the local density approximation (LDA) and the LMTO method for which one may perform the Wannier function projection procedure.¹⁰ The use of this procedure allows us to get the on-site Hamiltonian matrix for the Ru-4d states and all the hoppings between different sites. The projection was performed onto thirty Ru-4d orbitals (5 orbitals × 3 atoms × 2 formula units) in the local coordinate system, where the axis are directed to the nearest oxygens.

The diagonalization of the on-site Hamiltonian in a real space for each Ru leads to the order of the levels predicted by the local distortions. The tetragonal elongation of the RuₘO₆ octahedra results in two low-lying almost degenerate t₂g levels split from the higher t₂g orbital by ~330 meV. However, a close inspection of the Hamiltonian shows that the hopping integrals between Ruₒ and Ruₘ exceed 360 meV, which is, in contrast to naive expectations, even larger than the off-diagonal on-site matrix elements for the t₂g orbitals. Thus the orbitals on which the Ru-4d electrons tend to localize are determined not only by the crystal field created by the local surroundings (oxygens), but also by the inter-site matrix elements. This is mainly due to a face-sharing packing of the RuO₆ octahedra in the trimers, which allows a direct overlap between d orbitals on the neighboring Ru sites. Indeed, the nearest neighbors Ru-Ru distance across the common face 2.55 Å is even less than that in ruthenium metal, 2.65 Å.¹³ It is also quite important that the relevant orbitals here are 4d orbitals, which are more extended than 3d.¹⁴

In order to take into account the hoppings, we constructed the large 15 × 15 Ruₒ-Ruₘ-Ruₒ Hamiltonian for the trimer in a real space. Diagonalizing this Hamiltonian one obtains that
the lowest and highest in energy are the molecular orbitals which have the $a_{1g}$ symmetry with the largest contribution on the central Ru$_o$ ion. This is clearly seen in Fig. 4, where the highest in energy antibonding $a^*_{1g}$ molecular orbital is plotted. This orbital corresponds to the band, which has the energy $\sim$0.9 eV in the ZT direction.

Inspecting Fig. 4, one may see that the contribution of the Ru$_o$-$4d$ states to the antibonding $a^*_{1g}$ orbital should be the largest (the same is actually correct also for the bonding $a_{1g}$ wave function). This is easy to understand by solving the three-site ($i = 1,2,3$) problem with the single orbital per site in the tight-binding approximation. For simplicity the energies of each orbital are taken the same, $\varepsilon_i = 0$, and the hoppings, $t > 0$, are nonzero only between the nearest sites. For the linear cluster of three atoms the Hamiltonian is written as

$$H = \begin{pmatrix} 0 & t & 0 \\ t & 0 & t \\ 0 & t & 0 \end{pmatrix}. \tag{1}$$

The energy spectrum consists of the bonding ($b$), antibonding ($ab$), and nonbonding ($nb$) orbitals:

$$E_{ab} = t\sqrt{2}, \quad \psi_{ab} = \frac{1}{\sqrt{2}}(\psi_1 - \sqrt{2}\psi_2 + \psi_3), \tag{2}$$

$$E_{nb} = 0, \quad \psi_{nb} = \frac{1}{\sqrt{2}}(\psi_1 - \psi_3), \tag{3}$$

$$E_b = -t\sqrt{2}, \quad \psi_b = \frac{1}{\sqrt{2}}(\psi_1 + \sqrt{2}\psi_2 + \psi_3). \tag{4}$$

As a result one may see that the weight of the states corresponding to the middle, $i = 2$, atom to the bonding and antibonding wave functions is equal to 50%, while they do not contribute to the nonbonding molecular orbital at all. Thus the Ru$_m$-$t_{2g}$ states of the $a_{1g}$ symmetry are pushed away from the Fermi level due to the molecular orbital formation. Moreover, the shift of the rest of the Ru$_m$-$t_{2g}$ states downward, with the corresponding charge disproportionation, leads to the suppression of the Ru$_m$ 4$d$ partial DOS in the vicinity of the Fermi level. The Ru$_o$-$4d$ states in contrast form a well defined peak exactly at the Fermi energy.

The Stoner criteria cannot be applied directly to the partial DOS, but it is clear that the gain in the magnetic energy due to the spin splitting on Ru$_m$ will be minimal (because of the pseudogap in its partial DOS), while the loss of the band energy will be substantial. Thus in the band picture the Ru$_m$-$4d$ states are not expected to be polarized. In contrast, the Ru$_o$-$4d$ states can be easily magnetized. This is exactly what we observe in the magnetic GGA calculations.

### IV. MAGNETIC GGA CALCULATIONS

Several configurations were investigated in our magnetic GGA calculations (see Table I). The lowest in energy is the state where the spins on the Ru$_o$ both in the same and in the adjacent trimers are antiparallel ($\uparrow m \downarrow - \uparrow m \downarrow$). The partial DOS corresponding to this configuration are plotted in Fig. 5. One may see that there is no splitting between majority and minority spins of the Ru$_m$. Thus according to our calculation 1/3 of the Ru atoms indeed are nonmagnetic, exactly as observed in the experiment.$^5$

The Stoner criteria cannot be applied directly to the partial DOS, but it is clear that the gain in the magnetic energy due to the spin splitting on Ru$_m$ will be minimal (because of the pseudogap in its partial DOS), while the loss of the band energy will be substantial. Thus in the band picture the Ru$_m$-$4d$ states are not expected to be polarized. In contrast, the Ru$_o$-$4d$ states can be easily magnetized. This is exactly what we observe in the magnetic GGA calculations.
The magnetic moment on the Ru\textsubscript{m} appears only in the configurations with the FM order of the Ru\textsubscript{o} in the trimers. The ferromagnetically ordered spins of the Ru\textsubscript{o} create an exchange field on the Ru\textsubscript{m}, which slightly magnetize these ions. On the band-structure language the appearance of some magnetization on Ru\textsubscript{m} in a ferromagnetic state can be explained by the spin splitting of the Ru\textsubscript{m}-4d states due to their hybridization with the Ru\textsubscript{o}-4d states, which as we have shown above is large enough.

The magnetic moments on Ru\textsubscript{o} are smaller than 2\(\mu_B\) expected for \(S = 1\). This is a rather typical situation for the transition metal oxides (especially for those based on the 4d and 5d elements) and can be attributed to a strong hybridization with the oxygens. Because of the hybridization we also observe nonzero magnetic moments on some of the oxygens, which vary from 0.04 to 0.26 \(\mu_B\), depending on the magnetic configuration and oxygens crystallographic positions. The largest magnetic moment, 0.26 \(\mu_B\), was found on the oxygen atoms, which belongs to two neighboring trimers in the fully FM solution (\(\uparrow m \downarrow \downarrow m \uparrow\)).

The analysis of the calculation results presented in Table I shows that the magnetic contributions to the total energies of different solutions is not described by purely Heisenberg terms, like \(J_{ij}S_iS_j\). Indeed, if one compares the total energies of two solutions with the AFM order in the trimer (e.g., \(\uparrow m \downarrow \downarrow m \downarrow\) and \(\uparrow m \downarrow \downarrow m \uparrow\)) then the lowest will be the one with the AFM coupling between trimers. However, if one analyses another two solutions with the FM order in the trimer (e.g., \(\uparrow m \uparrow \downarrow m \uparrow\) and \(\uparrow m \downarrow \downarrow m \downarrow\)), it becomes clear that the lowest will be the one with the FM coupling between trimers. This is mostly related with the smaller magnetic moment on the Ru\textsubscript{m} ions in the \(\uparrow m \uparrow \downarrow m \downarrow\) configuration, and it may be a consequence of molecular orbital formation on trimers.

There are also two other contributions to the magnetic energy in addition to the conventional Heisenberg model, which have to be taken into account to describe magnetic properties of Ba\textsubscript{4}Ru\textsubscript{3}O\textsubscript{10}. This is the development of the magnetic moments on Ru\textsubscript{m} when the spins in the trimer are parallel) and on those oxygens, which are shared by two trimers (when the spins on the neighbor trimers are FM ordered). In each case the contribution to the total energy is \(-IM^2/4\), where \(M\) is the magnetic moment on the Ru\textsubscript{m} or O ions, and \(I\) — the Stoner parameter, which is approximately equal to the Hund’s rule exchange parameter for Ru (0.7 eV) and to 1.6 eV, as it was calculated in Ref. 15.

It is important to mention that only a fully AFM state, corresponding to the lowest total energy, is insulating in the GGA approach, without including electronic correlations (Hubbard’s \(U\)). This is related to the band narrowing caused by the antiferromagnetism. The small gap insulating ground state, obtained in the magnetic GGA calculations agrees with a semiconducting temperature dependence of the electric resistivity, observed in Ref. 4.

### V. CORRELATION EFFECTS

It is well known that for the description of the electronic and magnetic properties of the transition metal oxides one often needs to take into account strong Coulomb correlations, which can be incorporated in the calculation scheme via the LDA+U/GGA+U\textsuperscript{8} or LDA + DMFT\textsuperscript{16} formalism.

We repeated the total energy calculation for some of the magnetic configurations within the GGA+U\textsuperscript{8} approximation (as mentioned above, we took the values \(U = 3\) eV and \(J_H = 0.7\) eV, obtained in Ref. 3) and found that the account of the Coulomb correlations increases the band gap values, but does not basically change the order of the total energies for different magnetic configurations (compare Tables I and II). This confirms that the origin of the unconventional magnetic properties is not related to the correlation effects, typical for the localized electrons, but is largely due to two factors discussed above: the formation of molecular orbitals on Ru trimers and charge redistribution, with the increase of \(d\)-electron number on the middle ruthenium, Ru\textsubscript{m}.

### VI. SUMMARY

Summarizing, on the basis of \textit{ab initio} and model calculations we obtained the explanation of the unusual magnetic properties of Ba\textsubscript{4}Ru\textsubscript{3}O\textsubscript{10}, which consist of the Ru trimers coupled via corner-shared oxygens. The ground state is found to be an antiferromagnetic insulator, with antiferromagnetic ordering both within and between Ru trimers. The most surprising fact—the nonmagnetic nature of the middle Ru ions in each trimer—is explained to be a result of a combined action of the formation of molecular orbitals in the Ru trimers and of charge redistribution, with the increasing \(d\) states occupation on the middle Ru which is sandwiched between two other Ru ions with antiparallel spins. These unusual magnetic properties of Ba\textsubscript{4}Ru\textsubscript{3}O\textsubscript{10} are well explained by the band picture, and the electron correlations do not play a significant role in the formation of this magnetic state.
